Abstract

Introduction

Pulmonary sporotrichosis (PST) is a rare and neglected but severe disease. Its optimal management remains challenging, as recommendations are primarily derived from case reports. This study summarizes PST patients' presentation, diagnosis, management, and outcome.

Methods

Studies were identified through a search on Google Scholar and PubMed. The collected data included study characteristics, demographic data, risk factors, comorbidities, clinical status, presentations, imaging findings, diagnostic methods, disease locality, fungal species, treatment methods, complications, ICU admission status, and outcomes.

Results

Most of the studies were conducted in the USA (71.7%). In total, 34.7% of the cases were smokers, 30.7% had occupational exposure to dust and soil, 5.3% had contact with pets or roses or wooden materials, and 2.7% had environmental exposure. Overall, 32% of the patients were alcoholic, 29.3% had bacterial infections, 24% had respiratory or pulmonary diseases, and 17.3% were found to have HIV. The most frequently reported symptom was coughing (61.3%). The most common imaging finding was cavitary lesions (53.3%). The most commonly utilized diagnostic approach was sputum culture (69.3%). A combined conservative regimen was the treatment of choice in 26 patients (34.7%). The survival rate was 69.3%, with a recurrence rate of 5.8%.

Conclusion

The coexistence of multiple risk factors may trigger the disease. Its low incidence in endemic areas suggests the potential for missed or misdiagnosed cases. Treatment approaches include a combined conservative regimen or in combination with surgery. The survival rate is high, but the mortality rate should not be overlooked.

1. Introduction

Sporotrichosis is a subacute or chronic subcutaneous mycosis in tropical and subtropical regions. It is caused by dimorphic fungi of the genus *Sporothrix* [1,2]. The primary route of infection involves the etiological agent traumatically inoculating the subcutaneous tissues while handling soil or other organic materials containing conidia. Additionally, zoonotic transmission, particularly from infected cats, and inhalation of fungal conidia from the environment are different modes of infection [3]. In addition to the cutaneous form, the disease has rare manifestations, including osteoarticular, mucosal, central nervous system, and pulmonary involvement [1]. Pulmonary sporotrichosis (PST) is a rare manifestation with two distinct forms: primary and multifocal. Patients with the primary form typically have underlying respiratory conditions, primarily chronic obstructive pulmonary disease (COPD). In contrast, those with the multifocal form are mostly immunosuppressed, like diabetic, alcoholic, and HIV patients. The respiratory symptoms are not distinctive and can mimic those of tuberculosis (TB) and other endemic systemic mycoses [4]. This condition has gained increased recognition in recent decades due to the rise in reported cases. Early detection can prevent invasive treatment and complications [4-6]. Determining the optimal management for PST remains a challenge. Treatment recommendations are primarily derived from limited evidence in case reports, as conducting randomized controlled trials has been impractical [4].

This systematic review aims to summarize the presentation, diagnosis, management, and outcome of patients with PST. The reviewed studies were confirmed to have been published in legitimate journals [7]

2. Methods

2.1 Data sources and literature search

The study followed the guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). Studies published up to June 1, 2024, were identified through a comprehensive search on Google Scholar and PubMed. The search strategy included the following keywords: (pulmonary OR lung OR respiratory AND sporotrichosis OR rose gardener OR sporothrix OR sporotrichum). The search was limited to human studies published in English without date restriction.

2.2 Eligibility criteria

The inclusion criteria were confirmed cases of PST and studies that addressed its presentation, diagnosis, and treatment. Review articles, studies with incomplete data, and those published in journals on warning lists were excluded.

2.3 Study selection process

Initially, a researcher reviewed the titles and abstracts of the identified studies, followed by full-text screening based on eligibility criteria. A second researcher then re-checked this work to correct errors and reduce bias. Subsequently, eligible studies were selected for inclusion. In instances of disagreement,

a third author intervened to resolve the issues through discussion and deliberation.

2.4 Data extraction

One author extracted the data, which was then independently reviewed by another author to ensure accuracy. The data collected from each study included multiple parameters such as the first author's name, publication year, study affiliation and design, demographic characteristics, risk factors, comorbidities, clinical status, presentations, imaging findings, diagnostic methods, disease focality, fungal species, treatment methods, complications, intensive care unit (ICU) admission status, and outcomes.

2.5 Statistical Analysis

The extracted data was collected in an Excel Sheet (2019) and then analyzed for qualitative synthesis (descriptive) using the Statistical Package for the Social Sciences (SPSS, v. 27, IBM Co.). The data was presented as frequency, percentage, mean, standard deviation, or median with range.

3. Results

3.1 Study selection

The systematic search identified 87 studies. After eliminating duplicates (10), studies with incomplete data (3), and non-English articles (3), the titles and abstracts of 71 articles were screened. Of these, one study was excluded for being irrelevant. Full-text screening of the remaining 70 articles led to the exclusion of 24 more. Ultimately, 46 eligible articles comprising 75 PST cases were included in the systematic review [1,2,4-6,8-48]. A PRISMA flow chart illustrating this process is provided in Figure 1.

3.2 Characteristics of the Studies

Most of the studies were conducted in the USA (71.7%), followed by Brazil (8.7%). Case reports constituted the majority of studies (91.3%), followed by three case series (6.5%) and one cohort study (2.2%) (Tables 1 and 2).

3.3 Patient demography and clinical status

The patients' ages ranged from 11 to 79, with a mean of 45.8. The gender distribution was predilected toward males (80%), with a male-to-female ratio of 4:1. In total, 34.7% of the cases were smokers, 30.7% had occupational exposure to dust and soil, 5.3% had contact with pets or roses or wooden materials, and 2.7% had environmental exposure. Regarding comorbidities and health issues, 32% of the patients were alcoholic, 29.3% had bacterial infections, 24% had respiratory or pulmonary diseases, and 17.3% were found to be infected with human immunodeficiency virus (HIV). Only three cases (4%) had a positive history of the disease. Nineteen cases (25.3%) were known to be immunocompromised (Table 2).

3.4 Disease presentation, diagnosis, and treatment

The raw data for each study can be found in Tables 3 and 4. The most frequently reported symptom was coughing, occurring in 46 patients (61.3%). Other common symptoms included fever in 36 patients (48.0%), weight loss in 34 patients (45.3%), and malaise in 30 patients (40.0%). The most frequent imaging finding was cavitary lesions in 40 patients (53.3%). Lung infiltration was identified in 26 patients (34.7%), pulmonary nodules in 10 patients (13.3%), fibrosis in 7 patients (9.3%), and consolidation in 4 patients (5.3%). In most cases, the diagnostic

conservative regimen plus surgical intervention in 11 patients (14.6%). Surgical intervention alone was employed in one patient (1.3%), while six patients (8.0%) received no treatment or the data was unavailable. Admission to the ICU was required for five patients (6.7%). The overall survival rate was 69.3%; however, 15 patients (20.0%) succumbed to the disease. The outcome of the remaining eight patients (10.7%) were unavailable. Among the survived cases, three patients (5.8%) experienced a disease recurrence (Table 5).

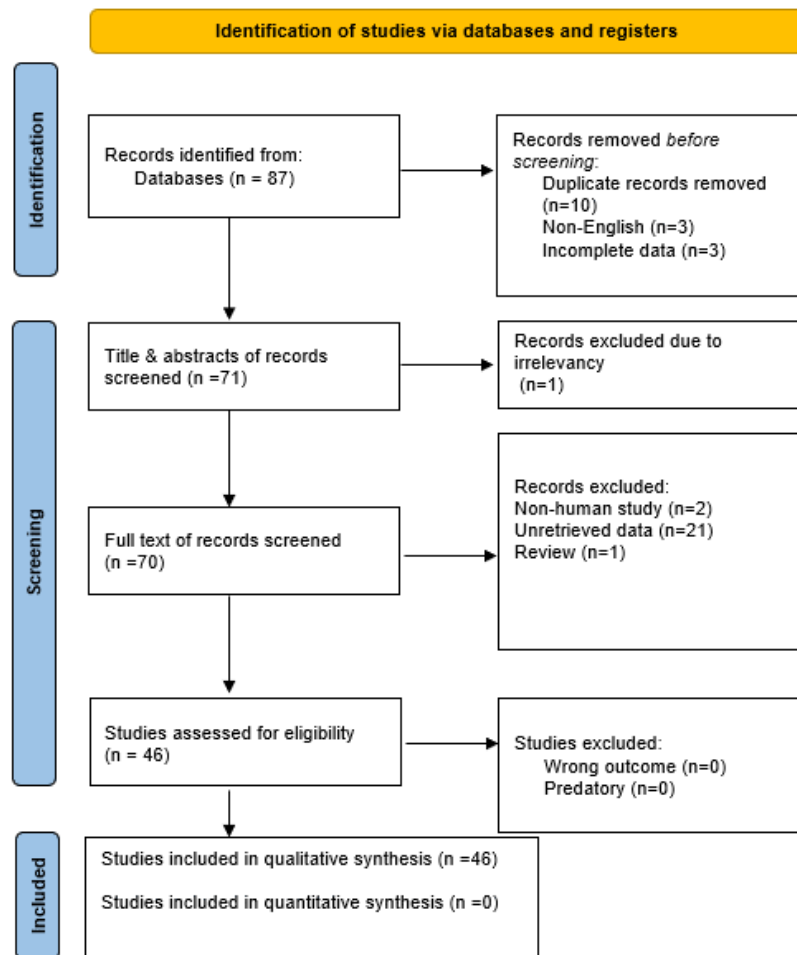

Figure 1. Study selection PRISMA flow chart.

approach was sputum culture, performed in 52 patients (69.3%). Other diagnostic methods included serology/titer in 16 patients (21.3%), bronchial washing culture in 13 patients (17.3%), histopathology in 13 patients (17.3%), bronchoalveolar lavage culture in 12 patients (16.0%), and tissue culture in nine patients (12.0%). Fifty patients (66.7%) had a primary PST, while 25 (33.3%) had multifocal disease. The most common species identified was *Sporothrix schenckii*, found in 58 patients (77.3%). *Sporothrix brasiliensis* was identified in 16 patients (21.3%) and *Sporothrix cyanescens* in one patient (1.3%). Treatment regimens varied among patients, with a combined conservative regimen being the most common, applied to 26 patients (34.7%). A single conservative regimen was used in 20 patients (26.7%), a single conservative regimen plus surgical intervention in 11 patients (14.6%), and a combined

4. Discussion

Human sporotrichosis, caused by the thermally dimorphic fungi *Sporothrix schenckii* complex, exhibits various clinical manifestations. It was first discovered in 1898 in a patient with subcutaneous abscesses and initially placed in the genus *Sporotrichum*. However, taxonomic revisions in the 1960s reclassified it under the genus *Sporothrix*. *Sporothrix schenckii* is now understood to be a genetically diverse cryptic species complex that includes *S. globosa*, *S. brasiliensis*, *S. luriei*, *S. mexicana*, *S. pallida* (formerly *S. albicans*), and *S. schenckii sensu stricto*. All species, except *S. pallida*, are capable of causing disease in humans [49].

The fungus typically thrives in tropical and subtropical climates across the American continents (notably Brazil, Uruguay,

Colombia, Peru, and Mexico), parts of Africa (especially sub-Saharan regions and South Africa), Asia (mainly Japan, India, and China), and Australia. Certain regions in South America, such as Abancay, are highly endemic areas, with sporotrichosis incidence rates reaching up to 60 cases per 100,000 annually [49]. However, PST's prevalence and incidence rates are not well-documented, even in hyperendemic regions. The epidemiology of reported PST cases is heavily influenced by publication bias, with nearly 90% of cases originating from the USA. In endemic regions, many PST cases are probably underreported or misdiagnosed [4]. During the first large sporotrichosis epidemic, which occurred in the mines of Transvaal, South Africa, 3,000 cases of the cutaneous form were reported, with no diagnoses of PST [50]. On the contrary, in 2019, Falcão et al. reviewed the Brazilian Unified National Health System and found that PST was the most common clinical form of sporotrichosis. This type accounted for at least 220 hospitalizations, representing 35.9% of all sporotrichosis

cases registered in hospitals from 1998 to 2015 [51]. Another study identified 1,322 cases of sporotrichosis in a large commercial health insurance database in the USA from 2012 to 2018. Among the cases where sporotrichosis was specified, lymphocutaneous was the most prevalent, with 68 cases, followed by PST, which accounted for 27 cases [52]. In the current systematic review of 46 studies, most (71.7%) were from the USA, followed by Brazil (8.7%), supporting the assumption that many PST cases may be misdiagnosed or overlooked in endemic regions. The infected species were *S. schenckii* in 58 cases (77.3%), *S. brasiliensis* in 16 cases (21.3%), and *S. cyanescens* in one case (1.3%).

Sporotrichosis presents in two clinical patterns: primary, a unifocal disease caused by direct inhalation of the fungus, and multifocal sporotrichosis, which can occur through direct inhalation of conidia followed by dissemination or, more commonly, via hematogenous or lymphatic spread from a distant site, often due to immunosuppression [1]. Due to its rarity, PST has traditionally been classified under "extracutaneous manifestations" of sporotrichosis. However,

this classification is misleading, as most cases of PST do not exhibit cutaneous symptoms [49]. A systematic review of 86 cases of PST reported that 64 cases (74.4%) were of the primary pulmonary form [4]. In line with the previous study, 66.7% of the cases identified in the present study were primary PST. This finding further supports the view that PST should not be regarded merely as an extracutaneous manifestation of sporotrichosis but as an independent entity.

It has been reported that over 80% of the cases are males, and the mean age of presentation is between 40 and 50 years [49]. The commonly suggested risk factors for primary PST include middle age, male gender, smoking, chronic corticosteroid use, chronic obstructive pulmonary disease, alcoholism, and immunosuppressive diseases like HIV [4]. Chronic alcohol abuse leads to lymphopenia and persistent activation of the T cell pool, which can impair T cells' ability to proliferate and respond to pathogens. This condition disrupts the balance between T-helper (Th)1 and Th2 responses [1]. A study conducted by Fichman et al. observed that most cases were males of low educational and economic backgrounds.

Table 5. Summary of disease presentation, diagnosis and treatment.

Variables	Frequency / Percentage
Symptoms/presentation*	
Cough	46 (61.3%)
Fever	36 (48.0%)

* For each case, multiple options may be present.

Predominantly, the patients exhibited multifocal disease with widespread skin lesions, and most (78.6%) were HIV-positive. They highlighted the crucial role of CD4+ T cells in controlling sporotrichosis, noting that these cells are also the primary target of HIV infection [1]. Nearly 50% of PST cases, whether in the primary or disseminated form, have identifiable occupational or environmental exposures to the fungus. These exposures include contact with plant materials, animals or animal products, and soil, particularly in bricklaying, gardening, or horticulture. In addition, heavy alcohol use has been noted in nearly 40% of reported cases. Patients with multifocal disseminated disease are more commonly immunocompromised (36.4%) than primary form (3.1%). Other associated immunosuppressive conditions include diabetes mellitus, chronic liver disease, malignancy, and autoimmune/connective tissue disorders, each occurring in less than 10% of cases. Additionally, about 25% of all cases have preexisting airway conditions such as COPD, asthma, and bronchiectasis [49]. Consistent with the literature, in this study, 80% of the cases were male, with a mean age of 45.8 years. In total, 34.7% were smokers, 32% were alcoholics, 30.7% had occupational exposure, 24% had respiratory or pulmonary disease, and 17.3% had HIV infection. Only four cases (5.3%) had contact with pets, roses, or other wooden materials, and two (2.7%) had environmental exposure. There were three cases (4%) with cancer and three with diabetes mellitus (4%). Only 19 cases (25.3%) were reported to be immunocompromised. These results indicate that the coexistence of multiple factors may be required to develop the disease.

Due to its nonspecific clinical presentation, particularly in cases of primary PST, the disease may be underestimated and misdiagnosed as other pulmonary infections, such as bacterial pneumonia and tuberculosis [1]. Up to 14% of primary PST cases are asymptomatic. When symptoms are present, the most common include cough, sputum production, and dyspnea in both primary pulmonary and multifocal disseminated forms. Constitutional symptoms such as fever, anorexia, and weight loss are prevalent in over 50% of patients, likely due to elevated levels of inflammatory cytokines such as tumor necrosis factors and interferons. Hemoptysis occurs significantly more frequently in primary PST than in multifocal disseminated disease, with rates of 42.2% and 9.1%, respectively. Coinfection with various bacteria (such as *S. pneumoniae*, *Klebsiella* species, *P. aeruginosa*, *Proteus* species, *S. aureus*, *A. israelii*, *M. tuberculosis*, and *M. avium complex*) and fungi (such as *Aspergillus* species, *Candida* species, and *Pneumocystis jirovecii*) has also been previously documented [49]. In the present study, coughing was the most common presentation (61.3%), followed by fever (48%), weight loss (45.3%), and malaise (40%). Hemoptysis was observed in 17 cases (22.7%), of which 14 (82.4%) were associated with primary disease, consistent with findings from the previous study. Twenty-two cases (29.3%) had bacterial coinfection, and six cases (8%) had fungal co-infection. Regarding bacterial coinfections, ten cases were infected with *M. tuberculosis*, three with *Streptococcus* species, three with *Klebsiella* species, two with *Staphylococcus* species, two with *E. coli*, and one each with *Actinomyces israelii*, *Pneumocystis jirovecii*, *Nocardia* species, *Enterococcus* species, and *Achromobacter* species. Among fungal coinfections, five cases involved *Candida* species, and one involved aspergillosis.

Pulmonary manifestations of *S. schenckii* are identifiable on chest X-rays or computed tomography scans. Comstock and Wolson were the first to recognize two distinct radiological patterns in pulmonary sporotrichosis: cavitary and noncavitary. These patterns are determined by whether the infection is confined to the lungs [53]. A systematic review conducted in 2013 revealed that most primary PST cases (77%) exhibited a cavitary pattern, whereas fewer than 10% of patients with multifocal disease showed cavities. Interestingly, 20% to 25% of patients with primary PST presented with noncavitary disease characterized by radiological findings such as reticulonodular infiltrates, consolidation, or fibrosis alone [4]. The most common imaging finding among reviewed cases was cavitary lesion (53.3%), followed by lung infiltration (34.7%). Of the 40 cases with cavitary lesions, 35 (87.5%) had primary PST.

The definitive diagnosis requires a fungal culture. Histopathological examination is not considered the most effective diagnostic method, as identifying the fungus in histological sections can be challenging [11]. In primary PST, the diagnosis is confirmed through the culture of sputum and bronchoscopic specimens. In contrast, in multifocal sporotrichosis, tissue samples from the skin and joints are typically used for diagnosis [9]. Among the reviewed cases, the

5. Conclusion

The coexistence of multiple risk factors, except only exposure to the fungus, may trigger the disease, including smoking, alcohol abuse, immunocompromised status, infection, malignancy, and other pulmonary diseases. Its low incidence in endemic areas suggests the potential for missed or misdiagnosed cases. Treatment approaches can include a combined conservative regimen or in combination with surgery. The survival rate can reach 69.3%; however, the mortality rate is significant at 20% and should not be overlooked.

Declarations

Conflicts of interest: The author(s) have no conflicts of interest to disclose.

Ethical approval: Not applicable, as systematic reviews do not require ethical approval.

Patient consent (participation and publication): Not applicable.

Funding: The present study received no financial support.

Acknowledgements: None to be declared.

Authors' contributions: FHK, BAA, and MNH collected data. KAA designed the study. FHF performed the data analysis. HOB, YMM, and SHK prepared the manuscript. HKA, HMA, BJHA, HSM, FA and TMM critically revised the manuscript. FHK and HOA confirmed the authenticity of the data. All authors approved the final version of the manuscript.

Data availability statement: Note applicable.

primary diagnostic approach was sputum culture (69.3%), followed by serology or titer (21.3%).

Treating both forms is challenging. For mild to moderate lung disease, the oral administration of itraconazole at 200 mg twice

daily for 12 months is recommended. In severe cases, a lipid formulation of amphotericin B (lipid complex or liposomal) at 3–5 mg/kg is advised until a positive response is observed. Afterward, the treatment can be switched to itraconazole 200 mg twice daily for 12 months. For localized pulmonary disease, a combination of surgery and amphotericin B therapy is suggested [1]. The present review found that 34.7% of cases were managed with a combined conservative regimen and 26.7% with a single conservative regimen. Conservative treatment combined with surgery was employed in 22 cases (29.2%). Only one case (1.3%) was treated with surgery alone. The severity of the disease necessitated ICU admission in five cases (6.7%). The survival rate was 69.3%, and recurrence occurred in three cases (5.8%). The limitations of this study stem from the nature of the included studies, as most were case reports, which may introduce bias into the findings. Additionally, the lack of experimental studies on the subject limited the potential for more comprehensive findings.
